# GALAXY SELECTION

## a) Redshift range : $0.025 < z < 0.05$

### Motivation:

1) We want to detect HI down to levels of a few percent in  $M(\text{gas})/M^*$  in about an hour of integration time.

2) We want to get an accurate estimate of the **total** cold gas mass with a single pointing of both the Arecibo telescope.

## b) Stellar mass range: $\log M^* > 10$

### Motivation:

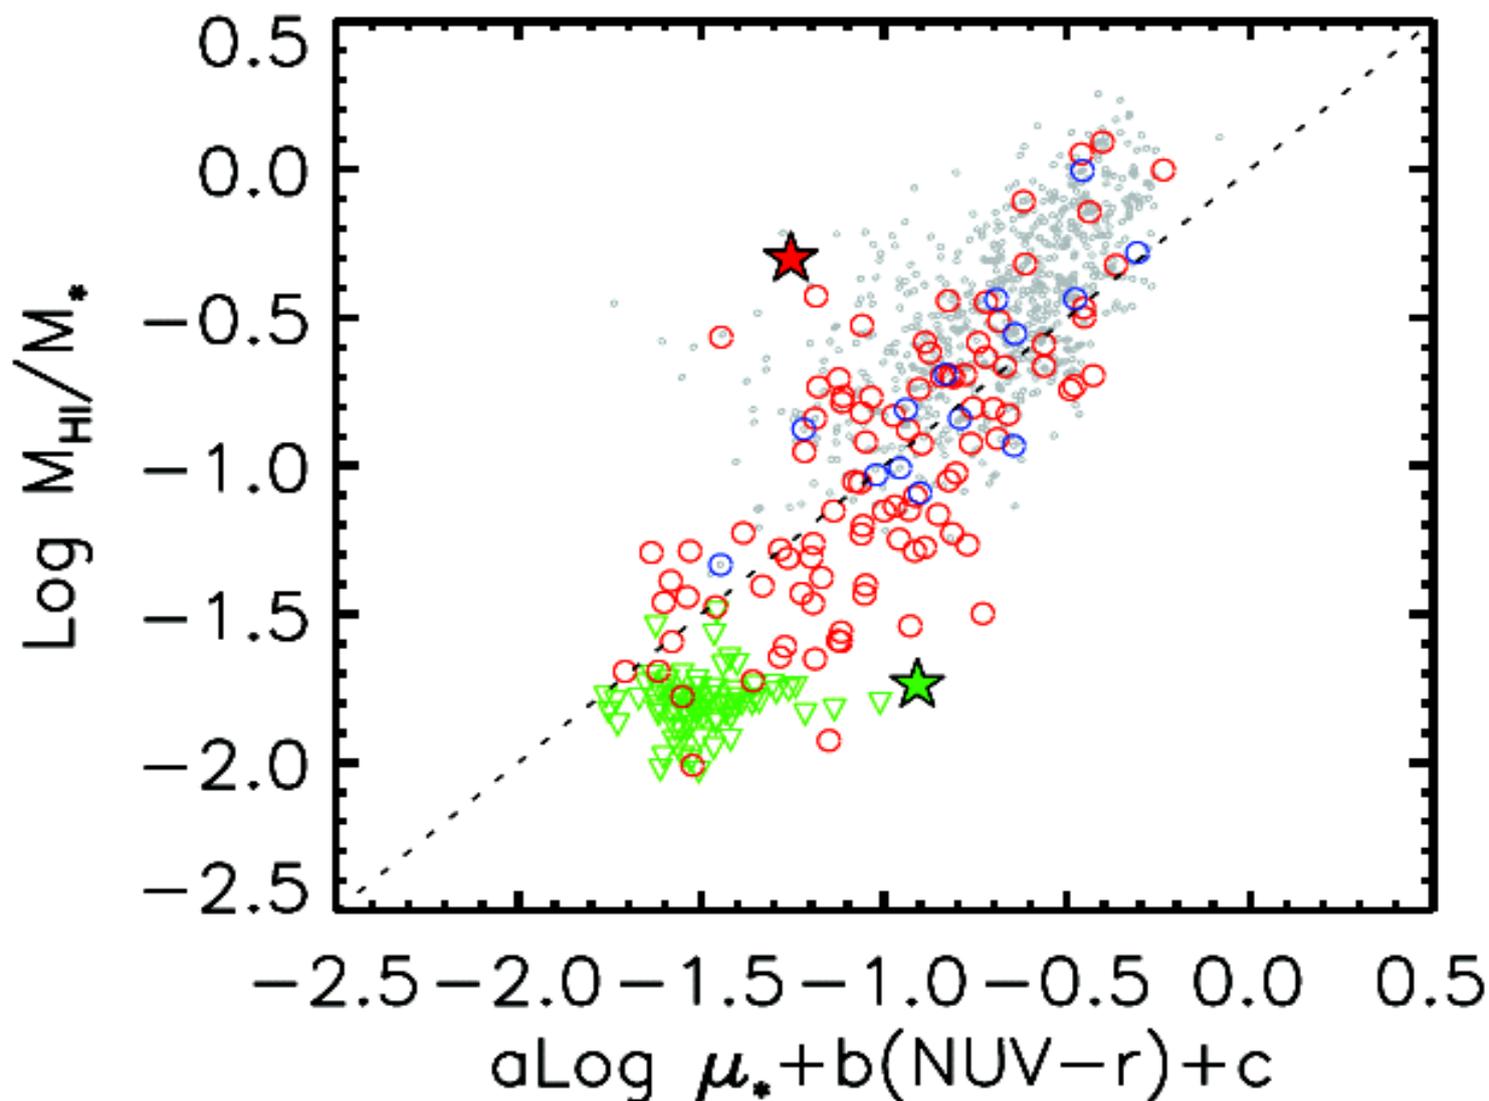

Span a range of stellar masses encompassing both “active” star-forming galaxies and “passive” systems => quantify how the transition between these two populations is reflected in their cold gas content. Avoid any selection on morphology, environment etc.

**OBSERVING STRATEGY:** Integrate until the galaxy is detected or a limiting HI mass fraction  $\sim 1.5\text{-}3\%$  is reached.

# THE STAR-FORMING POPULATION

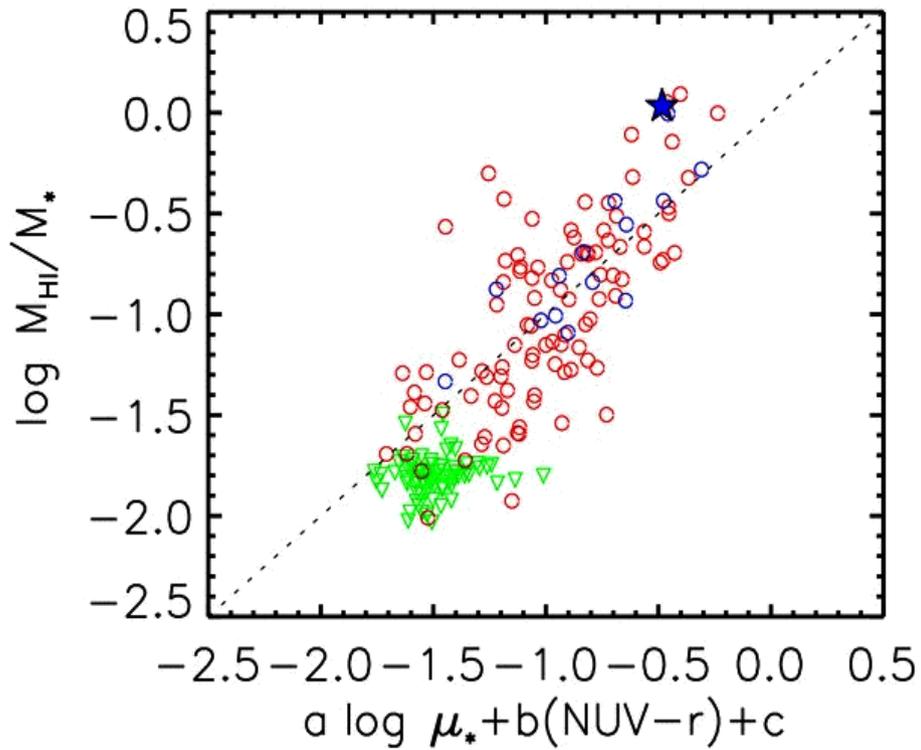

## An empirical best-fit “plane” for predicting HI mass fraction (Catinella et al 2010)

$$\Sigma_{\text{SFR}} \propto \Sigma_{\text{gas}}^n \implies \text{SFR}/M_* \propto (G/S)^n \mu_*^{n-1} \implies$$

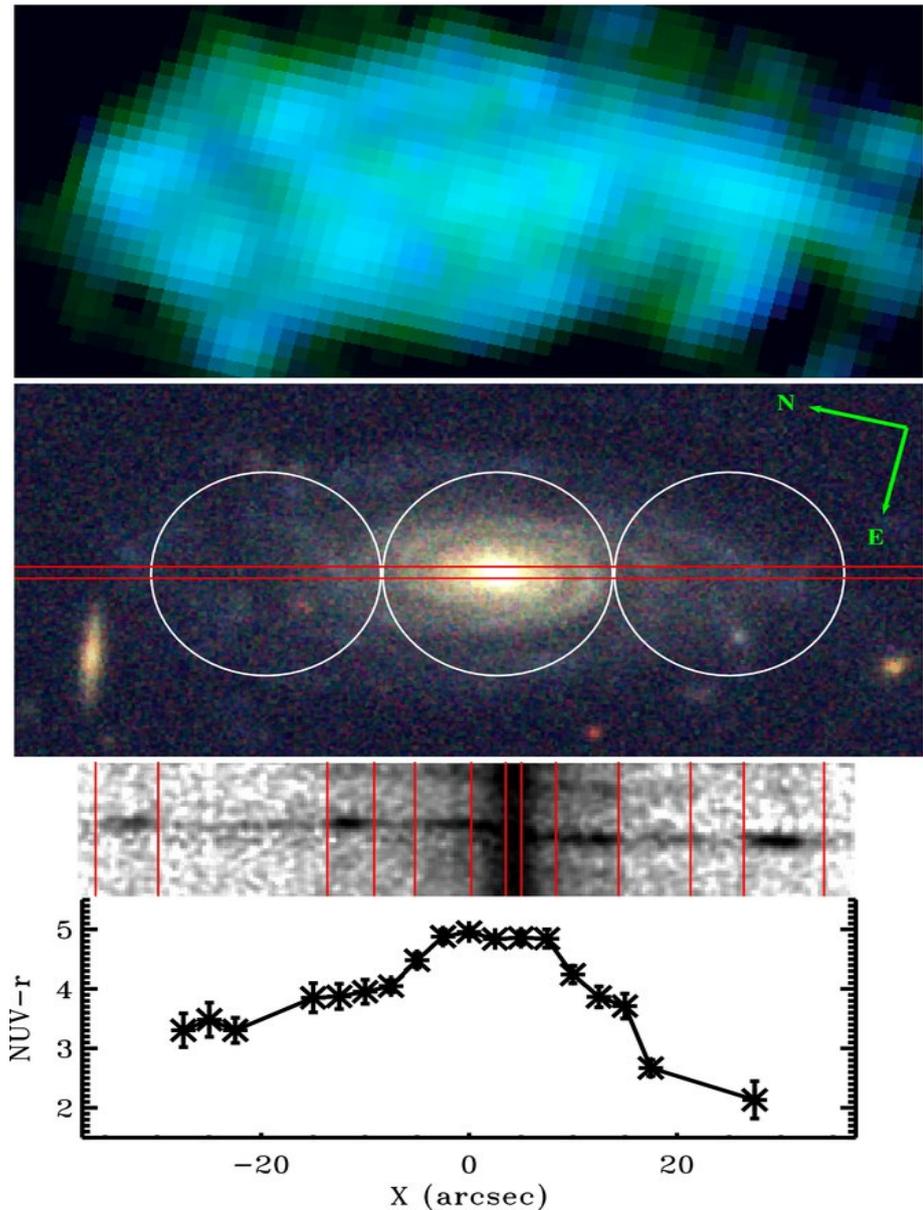

$$\log G/S = \log M_{\text{gas}}/M_* = a \log \mu_* + b \log \text{SFR}/M_* + c.$$

# UGC 8802: A Case Study of a Star-Forming Outlier from the HI “plane”

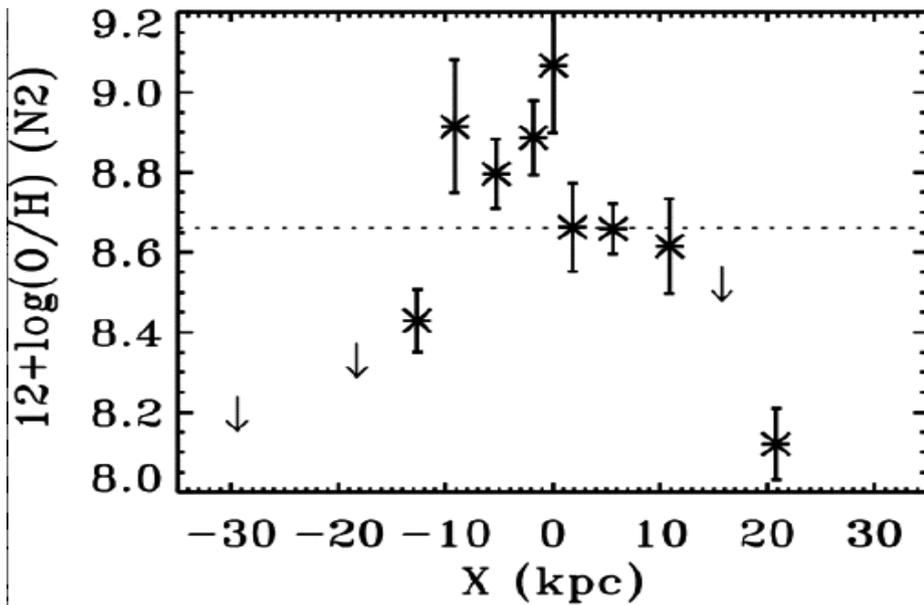

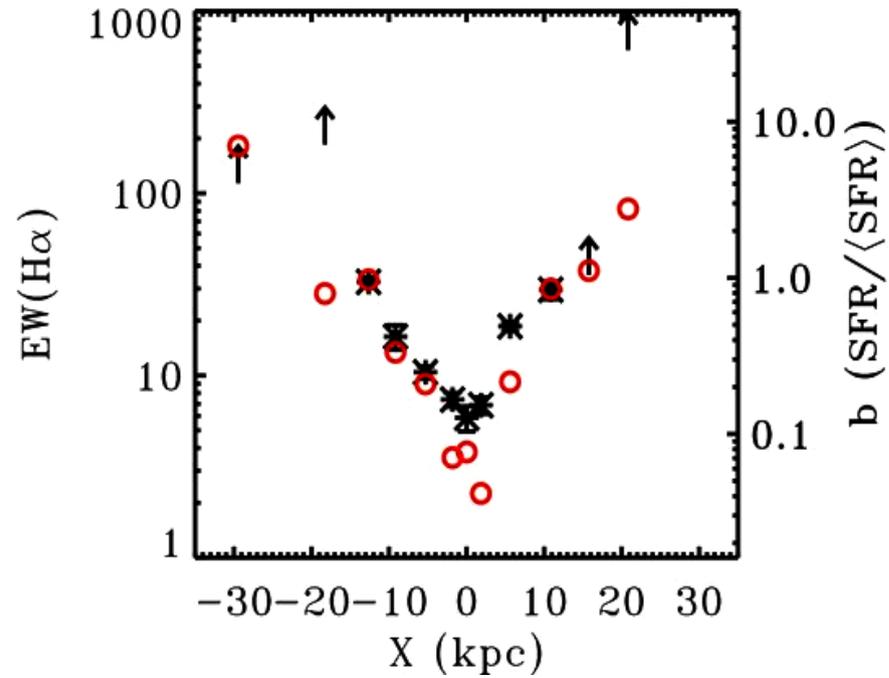

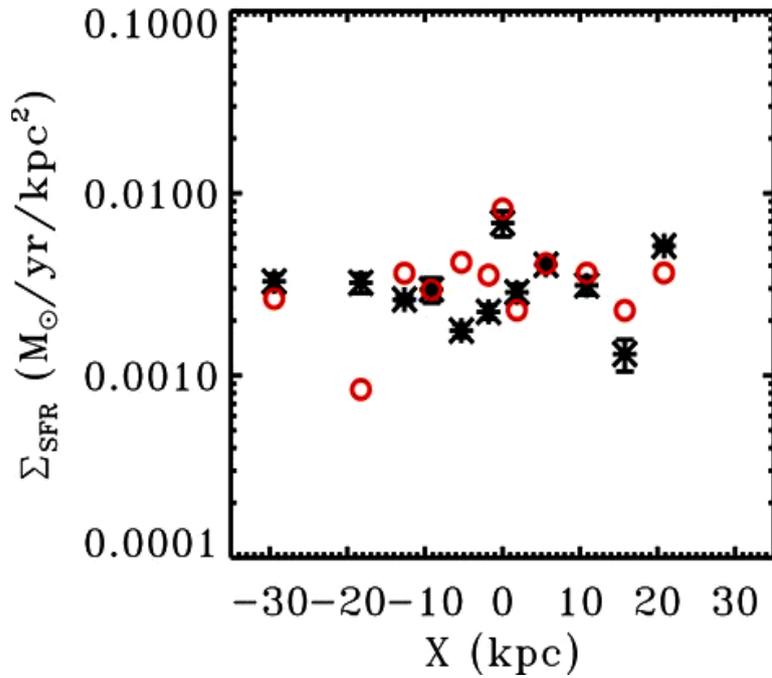

$$M(\text{HI}) = 2 \times 10^{10} M_{\text{sol}}$$

Moran et al 2010
